Bell’s palsy and SARS-CoV-2 vaccines

In light of the ongoing pandemic, development of vaccines to protect against SARS-CoV-2 infection and COVID-19 disease is an important public health priority. As of February 2021, two SARS-CoV-2 vaccines have received emergency use authorisation by the US Food and Drug Administration (FDA), both of which use mRNA technology. While the safety data are reassuring, phase 3 studies of both vaccines demonstrate an imbalance of cases of Bell’s palsy in the vaccine groups compared with the placebo groups. This Comment has three purposes: to briefly review the literature on the association of Bell’s palsy with vaccination, and vaccination for respiratory viruses such as influenza in particular, to consider biological mechanisms that might explain observed associations, and to reconsider statistical and epidemiological evidence from the reported safety data of the SARS-CoV-2 vaccine trials.

Associations between influenza vaccines and Bell’s palsy have been studied extensively (table). Elevated incidence of Bell’s palsy among recipients of an inactivated intranasal influenza vaccine was reported in a study conducted in 2000–01.1 Since this vaccine contained the Escherichia coli heat-labile toxin as a mucosal adjuvant, which undergoes retrograde neuronal uptake, it was suspected that heat-labile toxin could affect the seventh cranial nerve through such an interaction. Potential signs of Bell’s palsy have been reported following parenteral seasonal influenza vaccinations,2 and influenza H1N1 monovalent pandemic vaccinations.3,4 However, the association between parenteral influenza vaccines and Bell’s palsy was not reproducible in other studies.

A meningococcal conjugate vaccine showed a significant association with Bell’s palsy when administered simultaneously with other vaccines such as influenza, human papillomavirus, or diphtheria-tetanus-pertussis vaccines.5 A similar study did not detect a significantly increased risk, even though more than half of study participants received meningococcal vaccine simultaneously with other vaccines.6 Other vaccines studied have been reported to have no significant association with Bell’s palsy.

One theory suggests vaccines could be associated with autoimmune phenomenon, which is thought to occur via either mimicry of host molecules by the vaccinal antigen or bystander activation of dormant autoreactive T-cells.7 Such theorised associations have not withstood close scrutiny. The SARS-CoV-2 vaccines do not contain an exogenous adjuvant, but discussion between members of the FDA’s Vaccine

Table: Summary of studies reporting an association between vaccination and Bell’s palsy
Comment

and Related Biologic Products Advisory Committee and a sponsor (Pfizer) raised the possibility that the vaccine might induce innate immune activation from a combined effect of mRNA and lipids, potentially including interferon production. Such interferon production could transiently break peripheral tolerance, a hypothetical phenomenon invoked in several case reports.8,9

We conclude with a consideration of the statistical and epidemiological implications of reported safety data of the SARS-CoV-2 vaccine trials. Publicly available data from the Pfizer-BioNTech and Moderna vaccine trials suggest an imbalance in the incidence of Bell’s palsy following vaccination compared with the placebo arm of each trial. Combining data from both trials, among nearly 40 000 vaccine arm participants, there were seven Bell’s palsy cases compared with one Bell’s palsy case among placebo arm participants. This estimated rate ratio of roughly 7·0, suggests vaccination might be associated with Bell’s palsy (p=0·07).

Media reports have stated that the incidence of Bell’s palsy among participants of the Pfizer-BioNTech and Moderna vaccine trials is comparable to that observed in the general population. The FDA briefing on the Pfizer-BioNTech trial stated "observed frequency of reported Bell’s palsy in the vaccine group is consistent with the expected background rate in the general population", although this statement was removed from the subsequent FDA briefing on the Moderna trial. However, this reporting is based on a misconception, driven by a subtle distinction between rates and proportions, that has persisted in the lay media. The estimated incidence rate of Bell’s palsy in the general population ranges from 15 to 30 cases per 100 000 person-years. Since 40 000 vaccine arm participants were followed for a median of 2 months, the combined safety population receiving vaccine across the two trials represents roughly 6700 person-years of observation time for an expected incidence of Bell’s palsy of one to two cases, in line with the single observed case in the combined placebo arms.

Therefore, the observed incidence of Bell’s palsy in the vaccine arms is between 3·5-times and 7-times higher than would be expected in the general population. This finding signals a potential safety phenomenon and suggests inaccurate reporting of basic epidemiological context to the public.

Overall, both passive and active surveillance systems will be important to ensure vaccine safety. While we call for robust surveillance for potential mRNA vaccine-associated Bell’s palsy, we also note that Bell’s palsy usually self-resolves and we feel the available coronavirus mRNA vaccines offer a substantial net benefit to public health.
